The Berkeley Drosophila Transcription Network Project is developing a suite of methods to convert volumetric data generated by confocal microscopy into numerical representations of gene expression at cellular resolution. One key difficulty is that fluorescence microscopy can only capture expression levels for a few (2-4) gene products in a given animal. Here we report on a method for registering 3D expression data from different Drosophila embryos stained for overlapping subsets of target genes in order to build a composite atlas, ultimately containing collocation information for 1000s of genes. Our methods have also allowed the discovery of a complex pattern of cell density across the blastula that changes over time and may play a role in gastrulation.

Introduction

The output of animal gene transcription networks are complex 3D patterns of expression. These dynamically changing patterns can vary radically from one cell to the next and it is these spatial variations that principally define and determine the morphology and physiology of the animal. It is a grand challenge of biology to learn how to decipher the transcriptional information in the genome to the point where we can predict and model such intricate patterns. Researchers typically analyze spatial patterns of gene expression in multicellular organisms by visual inspection of photographic images of in situ hybridization experiments. A profound limitation of this approach is that it captures little 3D structure and typically provides only rough quantitative information. If we are to fully describe and understand this system, we first need a means to quantitatively record, with cellular resolution, these phenomenally complex expression

Our focus is on the network controlling early Drosophila melanogaster embryogenesis prior to gastrulation. This transcription network is initialized by the maternal deposition of mRNAs and proteins from a handful of regulators into the egg. About two hours after fertilization, zygotic transcription begins at which point the embryo is a syncytium with around 2,000 nuclei located along the perime-

ter. Thirty or so zygotic regulatory genes are transcribed initially, regulated by the maternally deposited factors. The Berkeley Drosophila Transcription Network Project [1] is focused on understanding interactions among these transcriptional regulators and their 1,000 target genes during the first 100 minutes of zygotic transcription. The availability of a complete genome sequence, powerful molecular and genetic tools, and the fact that there are only tens of specific factors regulating the early spatial patterning of transcription make *Drosophila* a desirable system for studying transcription networks.

Laser scanning confocal microscopy is a key enabling technology which allows us to measure the relative concentrations of gene products over a 3D volume. Using state of the art 2-photon equipment it is possible to image the entire *Drosophila* blastula with a resolution at which individual nuclei are still distinguishable. While fluorescence imagery is an incredibly rich source of data, it falls short of our goals since it can only provide expression data for 2 or 3 gene products in a given animal. How can we capture the expression level for a thousand different genes in a given cell?

Our approach is to composite expression measurements made from multiple images into a common model where the spatial distribution of more than three expression levels can be studied simultaneously. The key step is identifying corresponding nuclei in two different embryos and then using this correspondence to transfer the expression levels. If the embryos were identical and imaged in the exact same pose, finding correspondences would be easy. Unfortunately this is not the case, as morphology, including the number of nuclei, varies even between embryos at the exact same developmental stage. In addition, the imaging process introduces further complications in the form of variability in the pose, staining, and deformation of the embryo during fixing. The contribution outlined here is a technique for finding correspondence between embryos which is robust to these modes of variation.

¹When expression patterns are spatially disjoint, careful multiplexing techniques have provided up to 10 channels [9,8]

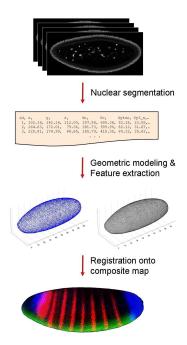

Figure 1: **Data-flow Overview**: Imaging each embryo produces a high-resolution volumetric image. Individual nuclei are segmented out using a DNA stain. The result is a "point cloud" containing the location of each nucleus and the apical, basal and nuclear fluorescence levels of the two other channels imaged along with morphological measurements such as the estimated nuclear and cellular volumes [10]. From this data, we produce a geometric model and extract features which capture the local pattern of expression for a reference gene in the neighborhood of each cell. These features along with the cell locations are then used in order to identify corresponding cells and register the embryo onto a composite model.

To our knowledge this three-dimensional registration problem at cellular resolution has not been studied in the past. The closest work to ours is that of John Reinitz and collaborators who used spline and wavelet based registration techniques in 1D along the anterior-posterior axis of the *Drosophila* embryo [12]. More recently they have considered a 2D version of the problem in order to register the lateral surface of an embryo which has been "flattened" before imaging [13].

Approach

Figure 1 gives an overview of our approach. We stain each embryo with a marker for DNA, a gene of interest, and a common "reference gene" which guides the registration process. Using the DNA marker, we segment out the location of each nuclei and record its 3D location along with expression levels in the surrounding cytoplasm [10]. Given two such sets of extracted cell locations, we formulate correspondence as an optimization problem whose solution si-

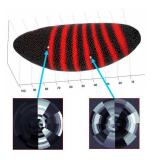

Figure 2: **Shape Context Descriptor**: For each nuclei we associate a shape context descriptor which is a spatial histogram of the expression levels of nuclei in the neighborhood of that point on the blastula surface. The polar spatial structure of the histogram bins provides robustness by making the descriptor more sensitive to the expression levels of nearby nuclei than to those of points farther away.

multaneously yields a mapping between nuclei as well as a smooth, non-linear spatial deformation that maps one embryo onto the other.

Our method for modeling shape variations falls into the category of "deformable templates" (e.g. [5]). To register a pair of embryos, we repeatedly alternate between two steps:

- Correspondence: For each cell in the first embryo, locate the "best" corresponding cell in the second embryo. This is formulated as a linear assignment problem with outliers where the matching weight includes a distance term and an appearance term dependent on the expression pattern. An efficient algorithm [4] finds solutions for thousands of nuclei in a few seconds
- Warping: Use the correspondences to estimate a global non-linear coordinate transformation that maps the first embryo to the second. We perform warping using the regularized thin-plate spline (TPS) which is a non-parametric model for representing flexible, global coordinate transformations [6, 11]. The thin plate spline is the higher dimensional generalization of the cubic spline. It has been shown effective for modeling changes in biological forms [3] and can be easily fit by solving a compact system of linear equations [14].

After warping, the embryos are better aligned making it easier to solve the correspondence problem, which improves the estimate of the transformation, bettering the alignment in the second round and so on.

The typical problem encountered when applying deformable template methods is that of establishing the initial correspondence between two embryos. The syncytial blastoderm has very little in the way of unique morphological structures for identifying particular cells. Even using the expression levels of one or two gene products at a point is not sufficient. We overcome this problem by using a richer spatial descriptor termed *shape context* (see Figure 2) which

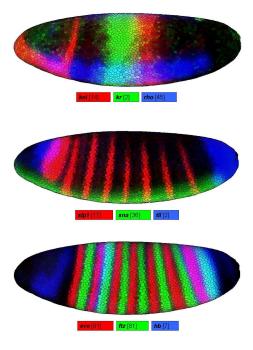

Figure 3: A preliminary composite map of gene expression demonstrating the output of our algorithm. For each nuclei location we have an estimate of the expression levels for 14 different genes. Here we show three different views of the composite model, visualizing particular subsets of genes products. When we have multiple embryos stained for the same gene, we can average these measurements on the composite model. As the staining process is stochastic, averaging multiple fluorescence measurements can decrease the variance in our estimate of the "true" in vivo expression levels. Numbers in brackets indicate how many embryos stained for that gene were averaged together.

has been successfully applied to a range of 2D and 3D shape matching problems in computer vision [2, 7].

Exploiting Correspondence to Build 3D Maps

Iterating the two steps of correspondence and warping will, given two similar but not identical embryos, yield a set of correspondences between nuclei in the two animals. Once a collection of embryos have been registered onto a common target embryo, we can use the correspondence to transfer expression levels onto that common target model. Figure 3 shows a preliminary composite map constructed in this fashion from 150 confocal images.

We can now easily visualize and study any combination of genes in this composite atlas. This capability should be quite useful in a high throughput setting with 1000s of genes since even producing the $O(N^2)$ raw images required to see every pairwise combination involves an infeasible number of in situ hybridizations. In contrast, our method only requires O(N) experiments, one for each of N genes paired with a reference gene.

In addition to expression patterns, the correspondence can also be used to average other quantities such as morphological measurements. For instance, we have begun to study the density of cellular packing in the blastoderm. The method described here has revealed a complex spatial pattern of nuclear densities which changes over time and may play an interesting role in the mechanics of gastrulation.
